Ilaris (Canakinumab) Receives a New Indication for the Treatment of Systemic Juvenile Idiopathic Arthritis

By Lisa A. Raedler, PhD, RPh

Ilaris (Canakinumab) Receives a New Indication for the United States with juvenile idiopathic arthritis in approximately 10% of children diagnosed with juvenile idiopathic arthritis in the United States.1,2 The classic symptoms of SJIA include pain in the small joints of the hands, wrists, knees, and ankles; rash; and a high, spiking fever of ≥103°F that can last for weeks to months.2 By definition, SJIA can present at any point until the age of 16 years. However, a long-term outcomes study found that the median age at diagnosis of SJIA was 4 years.3 The distribution of the disease by sex is roughly equal.4,5 Studies of long-term outcomes of juvenile idiopathic arthritis have demonstrated that disease-related morbidity continues to be evident in adulthood.4,6 Among adult patients with SJIA who were evaluated more than 16 years after diagnosis, 66% described joints with limited range of motion, 52% had joint pain, and 30% reported morning stiffness.6 Adult patients with SJIA also experience impaired quality of life and poor physical functioning, as well as long-term challenges with social functioning and sexual activity.5,8

Although analyses of healthcare costs associated with SJIA are few, it is clear that children with juvenile idiopathic arthritis consume inordinate amounts of healthcare resources. A 2007 study of Canadian children showed that the total annual average direct medical cost for patients with juvenile idiopathic arthritis was almost $1700 higher (2005 Canadian dollars; range, $875-$2500) than for the control patients without juvenile idiopathic arthritis.9 Higher costs for patients with juvenile idiopathic arthritis were related to specialist visits, diagnostic tests, and medication use.7 A more recent German study showed that the average total cost of juvenile idiopathic arthritis was highest among patients with seropositive polyarthritis and SJIA.7 The cost of medications, including biologics, comprised almost 50% of the total healthcare costs for these patients.8

Until very recently, the treatment options for patients with SJIA included methotrexate (Trexall); nonsteroidal anti-inflammatory drugs (NSAIDs); systemic corticosteroids; and tocilizumab (Actemra), an interleukin (IL)-6 inhibitor. Tocilizumab is indicated for patients with active SJIA aged ≥2 years and is administered once every 2 weeks as a 1-hour intravenous (IV) infusion.9 One additional medication was recently added as a new treatment option for this patient population. The availability of canakinumab for patients with SJIA offers an easier-to-use alternative for children and their families who wish to avoid the logistic and tolerability challenges associated with IV therapy given every 2 weeks.10 The efficacy of Ilaris, along with its monthly subcutaneous dosing, make it an exciting new option for children who are living with this debilitating disease,” said Daniel J. Lovell, MD, MPH, Associate Director, Division of Rheumatology, Cincinnati Children’s Hospital Medical Center, OH.11

Mechanism of Action

Canakinumab is a selective fully human monoclonal antibody that inhibits IL-1 beta, one of the proinflammatory cytokines that comprise the body’s immune system’s defenses.12 Excess production of IL-1 beta plays a prominent role in inflammatory diseases, including in patients with juvenile rheumatoid arthritis. Canakinumab inhibits inflammation by neutralizing IL-1 beta for a sustained period of time.13

Phase 3 Clinical Trials

Canakinumab was approved by the FDA for the treatment of SJIA on the basis of 2 randomized, multicenter, double-blind phase 3 clinical trials.14 Both trials enrolled patients who had a confirmed diagnosis of SJIA at least 2 months before enrollment in the study (mean disease duration at baseline, 3.5 years); active disease, defined as ≥2 joints with active arthritis (mean number of active joints, 15.4); documented spiking, intermittent fever (≥38°C) for at least 1 day within 1 week before study drug administration; and C-reactive protein >30 mg/L.15 Patients were allowed to continue treatment with stable doses of methotrexate, corticosteroids, and/or NSAIDs. The tapering of corticosteroid doses was allowed according to the design of the study.2,11,15

Trial Design

In study 1, patients with SJIA received a single dose of canakinumab 4 mg/kg (N = 43) or placebo (N = 41) via SC injection. Patients were then assessed for efficacy at day 15, and had a safety analysis done up to day 29.11,15 The SJIA study 2 had a 2-part design that included an open-label, single-arm, active-treatment period (part 1), followed by a randomized, double-blind, placebo-controlled, event-driven withdrawal design (part 2). Overall, 177 patients received canakinumab 4 mg/kg (maximum, 300 mg) in part 1 of study 2, and 100 patients received canakinumab 4 mg/kg (maximum, 300 mg) or placebo every 4 weeks in part 2 of study 2.11,15

The primary objective of study 1 was to demonstrate the superiority of a single dose of canakinumab relative to placebo in the proportion of patients who achieved ≥30% improvement in an adapted pediatric American College of Rheumatology (ACR) response criterion, which included the pediatric ACR core set (ACR 30% criteria for improvement [ACR30] response) and the absence of fever (temperature <38°C in the preceding 7 days) at day 15.11,13

The primary objective of study 2 was to demonstrate the prevention of flare with the use of canakinumab in patients with active SJIA. Flare was defined by a worsening of ≥30% in at least 3 of the 6 core pediatric ACR response variables, combined with an improvement of ≥30% in no more than 1 of the 6 variables, or the reappearance of fever not resulting from infection for at least 2 consecutive days.11,15

Efficacy: Study 1

The analysis of study 1 data revealed a significant improvement in patients receiving a single dose of canakinumab versus placebo at day 15.11 Table 1 presents the percentages of patients by pediatric ACR response rate.11 Among patients with SJIA who returned for their day 15 visit, the mean change in patient pain score (0-100 mm visual analog scale) was −50.0 mm with canakinumab (N = 43) compared with +4.5 mm with placebo (N = 25).11 The mean change in pain score among canakinumab-treated patients was consistent through day 29.11 All patients treated with canakinumab had no fever at day 3 compared with 87% of patients who received placebo.11

Efficacy: Study 2

Corticosteroid dose tapering. A total of 128 patients who entered part 1 (the open-label portion) of study 2, were taking corticosteroids. Of these, 92 patients attempted corticosteroid tapering. Of these 92 patients, 57 (62%) successfully tapered their corticosteroid doses.15 Almost half (N = 42 [46%]) of the patients discontinued treatment with corticosteroids.11,15

Time to flare. In part 2, the probability of having a flare over time was
significantly lower for the canakinumab-treated group versus the placebo group. Patients in the canakinumab group had a 64% relative reduction in the risk of flare compared with the patients receiving placebo (hazard ratio, 0.36; 95% confidence interval, 0.17-0.75).11,15

**Safety Profile of Canakinumab in SJIA**

The most common (≥10%) adverse drug reactions in patients with SJIA who received canakinumab were infections (ie, nasopharyngitis, upper respiratory tract infection, pneumonia, rhinitis, pharyngitis, tonsillitis, sinusitis, urinary tract infection, gastroenteritis, viral infection) received the drug. Antibodies against canakinumab were detected in 3.1% of patients who were treated with canakinumab for SJIA.11 No neutralizing antibodies were detected.11 No apparent correlation of antibody development to clinical response or adverse events was observed.11

**Macrophage activation syndrome.** Macrophage activation syndrome is a life-threatening disorder that can develop in patients with rheumatic conditions, in particular in patients with SJIA. Physicians should be attentive to any symptoms of infection or worsening of SJIA, because these are known triggers for macrophage activation syndrome. Of 201 patients with SJIA who were treated with canakinumab in clinical trials, 11 cases of macrophage activation syndrome were observed.11 In clinical trials, canakinumab did not increase the incidence of macrophage activation syndrome in patients with SJIA, but no definitive conclusion can be made at this point.11

**Immunosuppression.** The impact of treatment with anti–IL-1 therapy on the development of malignancies is not known. However, treatment with immunosuppressants, including canakinumab, may result in an increase in the risk of malignancies.11

**Conclusion**

For children and adolescents with SJIA, canakinumab offers clinically and statistically significant efficacy benefits, a favorable tolerability profile, and a convenient schedule and route of administration. Experts suggest that biologics, including canakinumab, are effective alternatives for children with SJIA who wish to avoid the potentially devastating toxicities of treatment with high-dose corticosteroids.10 Clinical studies are under way to assess the safety and efficacy of the prolonged use of various canakinumab doses, as well as to elucidate the role of canakinumab and other biologics relative to corticosteroids in patients with SJIA.10,17

†Weighted difference is the difference between the canakinumab and placebo response rates, adjusted for the stratification factors (ie, number of active joints, previous response to anakinra, and level of oral corticosteroid use). ACR indicates American College of Rheumatology; ACR30, ACR 30% criteria for improvement; CI, confidence interval; SJIA, systemic juvenile idiopathic arthritis.
